Hash functions

We have: some large, complicated data structure.
We want: a uniformly distributed table index.
Here's the general approach:

Data → Sequence of #s → 5, 3, 7, 8, 2, 4, 0, ...

Single machine used

Data → Sequence of #s Some data are just #s.
Others might be an array. If you have a more
complicated data structure, like a tree or a
graph, serialize it in some way.
Sequence of #s $\rightarrow$ machine word

Let $\mathbf{x}$ be the sequence of #s. Let $b$ be some base. Then, write the sequence as a polynomial in $b$:

$$a_0 + a_1 b + a_2 b^2 + a_3 b^3 + \ldots + a_n b^n$$

Evaluate this for some particular $b$.

Machine word $\rightarrow$ table index

Take $x \mod w$ where $x$ is the # above and $w$ is the table size.

Good hash function examples

Two common ways:

**Multiplication hash**

Let the table size $w$ be a power of 2 and let the base $b$ be odd. Then, just compute

$$a_0 + a_1 b + a_2 b^2 + \ldots + a_n b^n$$

allowing overflow of the machine word. At the end, take the last $\log_2 w$ bits to get the table index.

**Mod hash**

Let the table size be a prime $w$. Then compute $b_0 a_0 + a_1 b + a_2 b^2 + \ldots + a_n b^n \mod w$ by taking the remainder mod $w$ at every step. The base $b$ can be anything not divisible by the prime $w$, which is of the form $2^k$. The number $b$ should not be too close to a power of 2.

Reorder primes are your friends: multiply by them, divide by them.

Good practice: Pick a prime which is not close to a power of 10 or a power of 2. (For the mod hash, $w \neq 2^k$, for $\phi = \frac{w-1}{2}$ and some $k_1$ is good.)
Hash tables

Uniform hashing: with a good hash function, keys should be uniformly distributed in the table, with each key equally likely to go in each bucket.

Suppose you have $n$ balls and you throw them at random into $m$ bins. Then, on average, each bin has $\frac{n}{m}$ balls. This value, $\alpha = \frac{n}{m}$, is called the load factor of the hashtable. Then, the amount of time to search a random bin is $O(1 + \alpha)$. (1 cost upfront plus $\alpha$ balls found there)

Collision resolution

Two common methods of dealing with collisions:

- Chaining — discussed last lecture
- Open addressing — discussed next lecture

Table doubling

If we know the number of keys $n$ in advance, then we can pick a table size $m$ such that the load factor $\alpha = \frac{n}{m} \leq 1$. If we don't know the $n$ of keys in advance, then $\alpha$ may increase above 1 as we add more keys. To fix this, when $\alpha$ gets too large, we can pick a new table size $m' \geq 2m$ and rebuild a bigger hashtable with half the load factor. This is similar to the array length doubling used in, e.g., Python lists.
Python dictionaries

Items are pairs of the form (key, value)

Create dictionary:
```python
dict = {'algorithms': 5, 'cool': 42}
```

d. items() ➞ [('algorithms', 5), ('cool', 42)]
d['cool'] ➞ 42
d[42] ➞ KeyError
'cool' in d ➞ True
42 in d ➞ False

Python set is really dict where the items are just keys (not pairs).
